

Meteora DLMM Liquidity Pool Operations Analysis

Web3 Business Intelligence Portfolio Report | Solana | Public API snapshot

1. Executive Summary

This project treats decentralised liquidity pools as an operating product rather than a trading narrative. It combines a dated public API snapshot of 10 Meteora DLMM pools with protocol-level daily volume history to identify where liquidity capacity, trading demand and fee monetisation diverge.

At extraction (17 Sep 2026, 08:53 UTC), the sampled pools represented \$92,149,753 TVL, \$122,917,595 in 24-hour volume and \$209,465 in 24-hour fees. SOL-USDC was the largest sampled pool by 24-hour volume, accounting for 29.3% of sample volume. These are point-in-time diagnostic figures, not investment recommendations.

2. Business Context & Objective

For a decentralised exchange liquidity product, operators need to understand whether liquidity is being used efficiently, whether fee generation follows demand, and whether protocol activity is persistent or event-driven. The analysis answers three questions: (1) which pools show high volume relative to liquidity supplied; (2) where does gross fee intensity differ from utilisation; and (3) how volatile is daily protocol volume?

3. Data & Methodology

Data was retrieved from Meteora's public read-only DLMM API endpoints `/pools` and `/stats/daily/volume`. The pool snapshot contains TVL, 24-hour volume, fees, transactions, displayed APR/APY and token-pair attributes. Protocol history is filtered to the latest 60 positive daily observations. The included JSON responses preserve the exact source payloads; the Excel workbooks provide the transformation logic.

Core metrics: $\text{Volume} / \text{TVL} = 24\text{-hour volume} \div \text{current TVL}$ (liquidity-utilisation proxy). $\text{Fee Yield (24h)} = 24\text{-hour fees} \div \text{current TVL}$ (gross daily fee intensity). A 7-day moving average is used to reduce single-day volume noise. Neither metric is a return forecast.

Figure 1. Pool efficiency segmentation: TVL vs. 24-hour trading volume.

4. Findings & Operating Implications

Pool segmentation: A high Volume / TVL ratio can indicate strong liquidity utilisation and merits monitoring for depth, routing quality and LP retention. High TVL with low utilisation suggests a pool where operators should investigate incentives, token demand or capital efficiency. Fee yield should be assessed alongside utilisation because fee tiers and trading composition can create divergence.

Protocol trend: the latest available 7-day average daily volume is \$255,517,761. This is -10.4% versus the preceding 7-day average, so the portfolio view should distinguish persistent demand from a short-term event.

5. Recommendations

1. Build a weekly pool-health review prioritising high-volume pools with falling TVL or unusual transaction patterns. 2. Segment pools into utilisation / monetisation quadrants before changing incentives. 3. Pair volume spikes with qualitative event logs—new token launches, campaigns, routing changes or market moves—before deciding that growth is durable. 4. Extend the pipeline with wallet cohorts or position-level data if a business stakeholder needs LP retention analysis.

6. Limitations & Reproducibility

The pool table is a reproducible API-page snapshot rather than a full audited protocol census. TVL and displayed APR/APY are source-provided, time-sensitive values. The analysis does not make valuation, performance or investment claims. Re-run `build_project.py` before presenting figures as current; Power BI visuals should be refreshed from the latest workbook before presentation.

Appendix — Deliverables

01_Raw_Pool_Snapshot.xlsx — source snapshot and field definitions.

02_Meteora_DLMM_Operations_Analysis.xlsx — dashboard, benchmark, protocol trend and metric guide.

source_pool_snapshot.json and source_protocol_daily_volume.json — API payload archive.

build_project.py — reproducible refresh script.
